In the production of wholesome, fresh and frozen ready-to-cook poultry, the importance of rapid cooling to remove body heat is generally recognized. Methods of cooling in commercial use include ice chilling in a tank of slush ice and air chilling in a refrigerated room with moderate air currents. Regulations of the United States Department of Agriculture (1953) call for an internal temperature of the carcasses of 36 to 40°F within 24 hours. Freezing rooms should be equipped to freeze ready-to-cook poultry solid in less than 60 hours at temperatures of -10 to -40°F.

The object of the present investigation was to study the feasibility of using brine immersion to cool packaged warm eviscerated ready-to-cook poultry to 40°F and freeze it. Such procedures, involving packaging prior to cooling and combining the cooling and freezing operations in one step, are appealing from the standpoint of (1) minimizing contamination of poultry during handling operations, (2) reduction of overall handling and labor costs, (3) more rapid cooling than is realized by a slush ice or air chilling, and (4) elimination of a leaching of flavor from poultry during slush ice cooling as has been suggested by Pippen (1953). Such chilling would result in less shrinkage as compared to the air blast system, and also it should result in more uniform cooling and a higher quality end product compared to the variable results associated with tank cooling methods. In addition, it is believed that immersion cooling methods should make for a more effective utilization of refrigeration equipment.

Review of Literature

Much has been published on the cooling of poultry. In this paper only a selected portion of the literature will be cited in order to show the means available for chilling poultry and the problems involved. Sweet and Stewart 8 (1942) described a method of chilling poultry by means of a brine spray. When brine at 50°F was used, chickens and turkeys were chilled in 25 to 35 percent of the time required in air at 35°F. Stewart, Hanson, and Lowe W (1943) employed brine spray (Zurich-schenk process) at -5°F to freeze dressed poultry. They found that birds which are brine spray frozen within five hours after dressing could be stored up to six months before eviscerating with good retention of appearance.

The freezing of poultry has recently been reviewed by Koons (1952) and Gore (1953). It was pointed out that the air blast system with an air temperature of about -30°F was commonly used. Mennig and Morris (1953) reported ice chilling of broilers could be hastened by pumping air through the slush ice in cooling vats. More rapid chill-
ing was said to be a major step in the production of more uniform, better quality poultry. A so-called "jet-freezing" system was described by Simons (1953). This system of air freezing was originally devised to increase freezing efficiency and freezer capacity for poultry.

Baker (1958) found that the rate of freezing had an important bearing on the color and appearance of frozen turkeys. Rapidly frozen birds were light in color and attractive in appearance. The birds were progressively darker in color as freezing temperatures were raised from —20 to 0 and 5°F. He recommended that turkeys be frozen at a temperature as low as —20°F with good air circulation. Duncker and Hanks (1950) showed that the freezing rates of meats were significantly affected by the type of wrapping material used. Some wrapping materials were found to reduce the freezing rates as much as 50 percent.

**Experimental**

**Preparation and Packaging of Poultry**—The classes of poultry used in this investigation are summarized in Table 1.

The broilers, pouls, and stages were obtained from a nearby poultry grower and processor. The chickens were killed, scaled at 126°F, and the feathers removed at his poultry plant. The dressed birds were then immediately brought to the laboratory where they were eviscerated. The turkeys were killed, dressed, and eviscerated at a nearby turkey farm. Immediately after being eviscerated, they were placed in insulated containers and brought to the laboratory. These handling procedures resulted in a minimum loss of body heat prior to packaging and cooling.

The temperature of the birds during cooling and of the cooling medium was measured at 5-minute intervals by means of 24-gage copper constantan thermocouples and a 24-point Brown Indicating Electronik Potentiometer. Preliminary tests indicated that the points of slowest cooling in broilers, pouls, stages, and turkeys were in the thick portion of the breast and thigh. Thermocouples were located in each of these sections of each bird tested. In the packaged birds the thermocouples were located at the inside surface of the body cavity, and in unpackaged birds the thermocouples were located midway between the inside and outside walls of the bird at the areas of slowest cooling.

The packaged birds were packed in moisture-vapor resistant bags. Two thermocouples were passed through a hole just below the bottom of the bag and were located in the carcass of the bird, which was then vacuumed with a string. They were placed in the bag. Portions of the bag at the bottom, where the thermocouples were introduced, were cut to remove the lead wire and sealed with a metal clip. The bag was then vacuumized, sealed, and shrink-wrapped in the usual manner. In the unpackaged birds, the thermocouples were set in position and held in place by the trussing string.

**Chilling and Freezing Methods**—The equipment employed in making the chilling and freezing tests consisted of an insulated rectangular steel tank (100-gal capacity), a refrigeration unit, a 24-point indicating potentiometer, a 6-point recording potentiometer, and a resistance-type temperature controller. The tank was equipped with perforated pipes in the bottom to permit air to be admitted through the cooling medium to assure uniform temperature distribution. An evaporative coil was located above the perforated pipes to provide the necessary refrigeration. The coil was

Table 2. Chilling and Freezing of Poultry in a Liquid Medium

All packaged poultry were packed into moisture-vapor resistant bags which were vacuumed, clipped, and shrunk by dipping into water at 200°F. Unpackaged poultry were not wriggled in any manner but were placed directly in the cooling medium.
connected to a Freon-12 condensing unit located adjacent to the tank. A temperature controller was used to maintain the bath temperature for the 23, 6, and -20 F tests. Calcium chloride brine was used as the cooling medium for tests below 32 F. The top of the tank was covered and insulated with a blanket.

**Tests Conducted**

Time to Chill to 40 F and Time to Freeze to 15 F—Ten packaged birds and ten unpackaged birds of each class of poultry except the mature tom turkeys were employed in each test as summarized in Table 2. Five packaged mature tom turkeys were also used in each experimental variable. Chilling and freezing data were obtained for broilers, fowl, stage, young hen turkeys, and mature tom turkeys in the following cooling media: (1) slush ice at 33 F; (2) water at 33 F; (3) brine at 28 F; (4) brine at 0 F; and (5) brine at -20 F.

Data were not obtained for each weight class of poultry under all conditions. However, an effort was made to cover extreme conditions.

**Temperature Equalization**—In order to determine the practicability of chilling packaged poultry in -20 F brine for a short time, followed by holding under refrigeration at 36 F until the birds were cooled to 40 F, the following techniques were employed: Broilers, young hen turkeys, and mature tom turkeys, in sets of five birds of each class, were packaged in plastic bags and held for varying lengths of time in brine at -20 F. Three sets of broilers were immersed for 4, 6, and 15 minutes; three sets of young hen turkeys for 20, 45, and 80 minutes; and three sets of mature tom turkeys for 20, 45, and 60 minutes respectively. Upon removal from the brine, the birds were rinsed with cold water, placed in fiberboard cartons, and held in a 36 F walk-in refrigerator until no further cooling attributable to the chilling at -20 F occurred. Each of the sets of five broilers was held in a flat carton of 6-bird capacity. The turkeys were held in individual cartons. One set of broilers and a set of young hen turkeys were not boxed and were used as controls for this phase of the test.

**Results and Discussion**

A summary of results obtained in this investigation is presented in Tables 2 and 3.

Results of the chilling and freezing tests for the various classes of poultry studied are summarized in Table 2. Data presented represent those obtained with the slowest cooling bird in each instance. These results are presented graphically in Figures 1 and 2.

The poultry in each weight class, packaged in the moisture-vapor resistant bags, cooled more slowly than did the unwrapped birds. This difference in cooling rates is attributed partly to the fact that in the unwrapped birds the cooling medium in the body cavity is also very effective in heat removal, whereas in the packaged birds cooling was only from the outside of the bird. For a given cooling medium and bird class, it took from about two to three times as long to chill the packaged birds as the unwrapped birds to 40 F. However, if one regards these data in the light of present-day poultry chilling practice, which is the use of slush ice, the packaged poultry chilled in low temperature brines compares quite favorably with unwrapped birds in 35 F slush ice brines long enough to freeze throughout, a carcass temperature of approximately 15 F was taken as the end point in the freezing time determination. Here again, it took approximately twice as long to freeze broilers and young hen turkeys in the plastic bags as it did the unwrapped birds. But it took only five hours to freeze packaged 12-pound turkeys in -20 F brine. This is in marked contrast to the upwards of 60 hours required in some air freezing operations. Again, the major consideration is not the packaging, but the comparison of

**Fig. 4. Cooling rates of different weight classes of packaged poultry chilled in brine at -20 F, then held in refrigerator at 36 F in cartons.**
the relatively rapid brine cooling technique as compared with the present commercial practices of slower freezing in air. It appears that a one-step operation for cooling and freezing eviscerated birds would result in some noticeable saving in time, labor, and handling.

These investigations on cooling and freezing rates have yielded considerable data which, while interesting and useful, require a common basis for comparison and application in practice. Such a comparison can readily be made from Figure 3, which presents the data graphically on the basis of time to chill to 40 °F per pound with cooling media of different temperatures. In most cases rather good agreement was obtained for the different weight classes of poultry in a given cooling medium. In using this curve the time required per pound of bird to cool to 40 °F needs only to be multiplied by the weight of the bird to arrive at the total cooling time required for a bird of given size.

In order to arrive at freezing times per pound of packaged bird, data for broilers, young hen turkeys, and mature tom turkeys frozen in brine at —20 °F were analyzed. The time for the slowest cooling bird was taken as the time required per pound of bird to remove body heat and freeze to 15 °F. Although there was some variation in the freezing time for different sizes of birds, the results obtained indicate that the freezing time per pound of bird submerged in —20 °F brine is in the range of 20 to 30 minutes.

From the data summarized in Table 3 and from the cooling rate curves shown in Figure 4, it appears that chilling eviscerated, packaged poultry in —20 °F brine, followed by holding at 36 °F (normal refrigerated cold room), offers a rapid and effective method for removing the body heat prior to freezing or distribution to the fresh market. On the basis of these data, chilling times in —20 °F brine of 6, 35, and 45 minutes for ready-to-cook broilers, 12-pound ready-to-cook young hen turkeys, and 22 to 27-pound ready-to-cook mature tom turkeys, respectively, followed by holding in a refrigerator at 36 °F, should provide adequate chilling.

**Conclusions**

Chilling and freezing rate data were obtained for packaged and unpackaged poultry ranging in size from chicken broilers to stages, and from young hen turkeys to mature tom turkeys cooled by immersion in various liquid media at temperatures ranging from 33 to —20 °F. Data showing the time required per pound of hot eviscerated, packaged birds to chill to 40 °F are also presented.

In general, the freezing time per pound of packaged ready-to-cook birds immersed in —20 °F brine is in the range of 20 to 30 minutes. Thus, in —20 °F calcium chloride brine, actual freezing times to 15 °F observed for hot eviscerated, packaged broilers, 12-pound turkeys, and 25-pound turkeys were approximately 1 1/2, 5, and 7 hours, respectively.

Chilling packaged, ready-to-cook poultry in —20 °F brine, followed by holding in a cold room at 36 °F, offers a rapid and effective method of removing the body heat prior to freezing or distribution as a fresh product. Immersion times in —20 °F brine of 6, 35, and 45 minutes, for broilers, 12-pound turkeys, and 22 to 27-pound ready-to-cook turkeys, respectively, are indicated.

Immersion brine cooling provides an effective means of removing the body heat from and freezing packaged, ready-to-cook poultry. In practice, this process could be carried out in one operation.
